Abstract

Background: Coronavirus disease 2019 (COVID-19) was declared a pandemic in March 2020 by the World Health Organization (WHO). Severe COVID-19 is represented with acute respiratory distress syndrome (ARDS) that requires mechanical ventilation. Moreover, recent studies are reporting invasive fungal infection associated with severe COVID-19. It is unclear whether the prescription of immunotherapies such as corticosteroids, or severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection itself is risk factor for COVID-19-associated invasive pulmonary aspergillosis (CAPA). Hence, fungal infections present an additional uncertainty in managing COVID-19 patients and further compromise the outcome.

Case study: Here we report a case of SARS-CoV-2 complicated by invasive pulmonary aspergillosis (IPA) in a patient with no traditional risk factors for IPA. Admitted to ICU due to ARDS on mechanical ventilation, the patient deteriorated clinically with unexplained increased of fraction of inspired oxygen (FiO₂) requirement from 50% to 80%. Investigations showed borderline serum galactomannan, nonspecific radiological findings reported to be atypical for COVID-19, and the respiratory sample grew Aspergillus spp.

Main diagnosis: COVID-19 related fungal infection. The patient was treated with antifungal therapy for four weeks. He improved clinically after one week of starting antimicrobial treatment. After a prolonged ICU stay (87 days) due to infection control precaution, he was discharged from the ICU and moved to a long-term facility for further management and support.

Conclusions: This case highlights the diagnostic challenge in such cases, and the importance of early recognition of CAPA which can optimize therapy by administration of appropriate antifungal agents that may impact mortality.

First published: 01 Feb 2021, 10:58 https://doi.org/10.12688/f1000research.28424.1
**Background**

Invasive pulmonary aspergillosis (IPA) is typically thought to cause disease in immunocompromised hosts, particularly in neutropenic patients. In the last two decades, it has been more commonly recognized in critically ill patients, particularly those with severe acute respiratory distress syndrome (ARDS). An increasing number of IPA cases complicating severe influenza have been reported following the H1N1 influenza pandemic in 2009. Vanderbeke et al. described 128 cases published between 1952–2018. In late December 2019, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) emerged as a public health emergency and has spread globally. Co-infections among patients with coronavirus disease 2019 (COVID-19) are currently well described in the literature. Chlamydia pneumoniae, Mycoplasma pneumoniae, and human metapneumovirus are among the common pathogens identified. Intensive care unit admission is required in around 5–30% of patients with COVID-19. IPA has started to be recognized in severe COVID-19 infection, with multiple case series of severe COVID-19 pneumonia complicated by IPA having been reported since the start of the pandemic. Here we report a case of IPA that was diagnosed in a patient with severe COVID-19 infection.

**Case**

We report the case of a 29-year-old Saudi male security guard known to have diabetes mellitus and chronic kidney disease. He was admitted to hospital at the end of May 2020 as a case of COVID-19 pneumonia that was complicated with diabetic ketoacidosis and required admission to the intensive care unit (ICU). He rapidly deteriorated with progression to ARDS, requiring intubation and mechanical ventilation. He also suffered a cardiac arrest that required resuscitation for 12 minutes. He received Lopinavir/Ritonavir and Ribavirin along with Ceftriaxone in the referring hospital (dosage unknown). He was then transferred to the King Faisal Specialist Hospital and Research Centre (KFSHRC) around six days after his initial diagnosis for further management.

On day 0 of ICU admission at KFSHRC the patient was deeply sedated on intravenous (IV) propofol 150mg/hour and fentanyl 100mcg/hour, measured temperature 34.7 °C, intubated on pressure control ventilation requiring FiO₂ 50% and positive end-expiratory pressure (PEEP) 8 cm H₂O. He required IV norepinephrine 0.02–0.2 mcg/kg/min to maintain his mean arterial blood pressure above 65 mmHg. His blood workup on day 0 was white blood cell count (WBC) 8.28 x10⁹ / L (3.9–11 x 10⁹ / L), absolute lymphocytes count 0.5 x10⁹ / L (1.50–4.30 x 10⁹ / L), platelet 54 x10⁹ / L (155–435 x 10⁹ / L), creatinine 603 umol/L (64 – 115 umol/L), and galactomannan antigen (AG) 0.48 (>0.5 reactive). A beta D-glucan test was not done as it was not available.

The patient was started on continuous renal replacement therapy (CRRT); his clinical status deteriorated with increased ventilation requirement of FiO₂ 50% to 80%, PEEP 8 to 16 cm H₂O on day 4. A chest X-ray showed multiple bilateral ill-defined patchy opacities in the right lower lung zone (Figure 1). A computed tomography (CT) scan for his chest was done and showed multiple bilateral patchy ground-glass opacities (Figure 2, Figure 3). Bilateral lower lobe consolidations with air bronchogram showed greater involvement of the right lower lobe, while an unenhanced CT of the brain demonstrated hyperdense foci seen in the left inferior frontal, right parietal lobes with surrounding edema, and right central sulcus compatible with intra-parenchymal hemorrhage and subarachnoid hemorrhage, respectively. A follow-up MRI of the brain was obtained, showing an increased gyral pattern of T1 and FLAIR sequence, as observed in the bilateral occipital, bilateral frontal, and...
right parietal lobes, likely related to laminar necrosis from the anoxic-ischemic event. Gradient recalled echo (GRE) sequence showed scattered areas of blooming artifacts that are likely to be related to recent extensive hemorrhage. The brain findings were suggestive of hemorrhage and hypoxic injuries of vascular causes of previous cardiac arrest events.

On day 0, the patient was started on hydroxychloroquine 400mg orally every 12 hours for 1 day, followed by a maintenance dose of 200mg every 12 hours and azithromycin 500mg orally once followed by a maintenance dose of 250mg daily, respectively, for a total duration for 5 days. His antimicrobial therapy was escalated to Meropenem 0.5 gm IV every 12 hours. He continued to worsen, and thus his septic screen was repeated. His blood and urine culture remained negative.

Tracheal aspirate culture on day 0 grew *Aspergillus fumigatus* and *Aspergillus flavus* (Figure 4a, Figure 4b, Figure 5a, Figure 5b). Bronchoscopy was considered; however, it was not done due to concerns of COVID-19 transmission to the house staff. The patient was then started on dual antifungal therapy (day 4) for 1 week; Voriconazole 400mg orally every 12 hours as a loading dose, then 200mg every 12 hours as maintenance. In addition, the patient was given Caspofungin 70mg IV as a loading dose, followed by 50mg daily. After this Voriconazole monotherapy therapy (200mg orally every 12 hours) for a total duration of four weeks was completed in the hospital. One week after starting antifungal therapy (day 10 in the ICU), the secretions improved and the ventilator setting was decreased to FiO₂ 30%. Unfortunately, the patient on day 5 of ICU admission was found to be in a vegetative state secondary to anoxic brain damage post-cardiac arrest. The Glasgow Coma Scale was GCS 10/15 on tracheostomy.

The patient had a prolonged ICU stay due to infection control precaution; his stay was complicated with rhabdomyolysis, difficulty to wean him from ventilation, nosocomial infection after 30 days of ICU admission, and persistent COVID-19 virus shedding up to 73 days. The patient was then moved to a long-term facility (on day 87) after discharging him from the ICU.

**Discussion**

This case further supports the association between IPA and severe COVID-19 infection. It highlights the importance of early diagnosis and treatment of this serious complication that
can impose increased mortality. The diagnosis of IPA in patients in ICU without classical risk factors like neutropenia remains challenging\textsuperscript{9,10}. Multiple studies from China have reported different rates of Aspergillus infections among patients with COVID-19. The estimated rates of Aspergillus co-infection in these combined studies are as follows: in Jiangsu province, 60/257 (23.3%), Zhejiang province, 8/104 (7.7%); and lastly, Wuhan, 13/48 (27%). All these reported CAPA cases lack standardization in diagnostic criteria and use specific definitions to identify and define CAPA\textsuperscript{10,11}. A European case series reported severe COVID-19 pneumonia complicated by IPA. All 27 cases were for patients admitted to the ICU, the majority of whom were intubated. The median duration between CAPA diagnosis and symptom onset was six days. Aspergillosis diagnosis was as early as three days post ICU admission or as late as 28 days\textsuperscript{10}. Of the 27 patients, 12 (44%) received corticosteroids during their ICU stay, and 19 (70%) were treated with mould-active antifungal medication\textsuperscript{1–3,4}. Bartoletti and colleagues found 22 (73%) of the 30 patients who were diagnosed with CAPA received Tocilizumab, and 18 (60%) received corticosteroids\textsuperscript{9}. Mixed fungal infection similar to our case was reported in two patients in a study from Pakistan, one with A. flavus and A. fumigatus diagnosed as CAPA, while a second patient was thought to be colonized with A. flavus and A. niger\textsuperscript{12}. Diagnosis is challenging due to the difficulty in differentiating between colonization and active disease in positive culture cases. Recently Arastehfar et al. suggested that galactomannan (GM) testing of bronchoalveolar fluid (BALF), or even of tracheal aspirates, may support CAPA’s diagnosis\textsuperscript{13}, though the test has not been validated for these specimens and cut-off values are not yet established.

Spanish tertiary hospitals carried out a retrospective study in patients with confirmed SARS-CoV-2 by PCR who isolated Aspergillus spp. in respiratory samples from bronchial aspirates (BAS) and bronchoalveolar lavages (BAL). Galactomannan assays were performed in serum and/or BAL with a cut-off index of 0.5 for both samples. COVID-19 associated IPA cases were classified according to the European Organization for Research and Treatment of Cancer/Invasive Fungal Infections Cooperative Group and the National Institute of Allergy and Infectious Diseases Mycoses Study Group EORTC/MSG criteria\textsuperscript{13} and Aspergillus algorithm for use in critically ill patients AspICU algorithm\textsuperscript{14}. Aspergillus spp. were grown in ten patients from respiratory samples. Seven patients were intubated in the ICU. All isolates were detected from deep respiratory samples: eight BAS one sputum and one BAL. Galactomannan analyses were run in only three patients, one with positive values in both serum and BAL ((1.97, 3.87) and another with repeated positive values in BAL samples (2.16, 1.11). The third patient had a negative serum galactomannan test (0.22)\textsuperscript{15}.

Performing bronchoscopy and obtaining a bronchial wash is challenging in patients with COVID-19. It carries a significant risk of transmission to healthcare workers, which further complicates the diagnosis of IPA in this patient population\textsuperscript{16}. A surveillance strategy for fungal co-infections in intubated patients with COVID-19 was done by Brown et al.\textsuperscript{12} utilizing weekly serum1–3–B-D-glucan, galactomannan Aspergillus enzyme immunoassay (EIA) and Aspergillus PCR from bronchoalveolar lavage or endotracheal aspirates. A total of 62 patients were examined, and a galactomannan test of tracheal aspirates was performed for 85 samples; positive results were seen in six out of 62 patients, of which positive Aspergillus PCR was seen in five out of the six, and two grew Aspergillus fumigatus in culture. CAPA was clinically suspected in two patients. One of these patients’ GM from BAL was not performed. Whether galactomannan positivity of endotracheal aspirates is a marker for CAPA or reflects upper airway colonization is not clear. It should be noted that none of their cases met the definition of CAPA\textsuperscript{17}.

The radiological differentiation between IPA and COVID-19 is often complex, as the radiological changes in IPA in non-neutropenic patients are diverse and non-specific. For instance, ground-glass opacities and dense consolidation are often found in COVID-19 and IPA\textsuperscript{18–20}.

To the best of our knowledge, this is the first reported case of mixed fungal infection in COVID-19 in the Middle East region. This case report further supports published data about severe COVID-19 and invasive fungal infection. Diagnosis of IPA in critically ill patients with COVID-19 in ICUs remains a challenge. The difficulties we faced were that the CT chest scan showed left lower lobe nodules with surrounding faint ground-glass densities which are not sufficient to define CAPA, while tracheal aspirate cultures positive for the presence of A. fumigatus and A. flavus cannot differentiate between colonization or true invasion. Obtaining future tests from BAL to support the diagnosis is complicated by the restriction in preforming bronchoscopy in patients with COVID-19 due to the risk of aerosol generation. The accuracy of serum galactomannan to diagnose IPA would increase if consecutive tests were performed to override its poor sensitivity in IPA detection in
Conclusions

IPA can complicate severe COVID-19 pneumonia. The diagnosis of CAPA is often challenging and requires a high index of suspicion. A constellation of clinical, biochemical, microbiological, and radiological criteria needs to be incorporated to establish the diagnosis. Timely diagnosis and management are required for better outcomes.

Data availability

All data underlying the results are available as part of the article and no additional source data are required.

Consent

Written informed consent for publication of their clinical details and clinical images was obtained from the relative of the patient.
An interesting report on an emerging clinical problem in the context of the ongoing SARS-CoV-2 pandemic. The authors describe the case in reasonable detail, its clinical progression and outcome. The discussion included a good contextualization of the case in the light of the salient knowns in the area. I suggest the authors consider the following comments to further improve their manuscript:

1. The first letter of an antimicrobial agent’s genetic name should not be capitalized when mentioned mid-sentence (examples from the manuscript: caspofungin, voriconazole, meropenem, lopinavir/ritonavir, ribavirin, and ceftriaxone).

2. SARS-Co-2 is the virus, while COVID-19 is the disease. The following expressions are incorrect: “COVID-19 transmission”, “persistent COVID-19 virus shedding”, “COVID-19 infection”.

3. Was the patient intubated in the referring hospital? If so, what was the timeframe between intubation and day 0 ICU in KFSHRC?

4. Did the patient receive corticosteroids, tocilizumab, sarilumab, or baricitinib in the referring hospital or in KFSHRC? It should be possible to obtain those details from the referring hospital? State if none was given.

5. It would be useful to comment in the discussion on the isolation of Aspergillus species from baseline BAL (day 0).

6. It would be useful to comment on combination AFT for IPA.

7. What are the prevailing Aspergillus species in Saudi Arabia? Is the isolation of A. flavus unusual?

8. Are there any other reports of CAPA from the Middle East or the Gulf region?
9. The article below is a comprehensive review of CAPA reports up to August 2020¹. The authors might find it useful for their discussion.

Thank you

References

Is the background of the case’s history and progression described in sufficient detail?
Yes

Are enough details provided of any physical examination and diagnostic tests, treatment given and outcomes?
Partly

Is sufficient discussion included of the importance of the findings and their relevance to future understanding of disease processes, diagnosis or treatment?
Partly

Is the case presented with sufficient detail to be useful for other practitioners?
Partly

Competing Interests: No competing interests were disclosed.

Reviewer Expertise: Infectious diseases in immune compromised hosts and critically ill patients

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard, however I have significant reservations, as outlined above.

Author Response 12 Mar 2021

Hanan AlBasata, King Faisal Specialist Hospital and research center, Riyadh, Saudi Arabia

Thank you for your review and comments, the following has been done in response to your valuable input:

Comment 1: edited.

Comment 2: Changed.

Comment 3: added.

Comment 4: Yes, he did receive dexamethasone in KFSH, added to the manuscript.

Comment 5: Added.
Comment 6: Added.

Comment 7: A paragraph was added for the most prevalent spp. locally and globally.

Comment 8: At the time of the writing no reported cases, however recently a case series in Kuwait was published and this was added in the discussion.

**Competing Interests:** No competing interests were disclosed.

The benefits of publishing with F1000Research:

- Your article is published within days, with no editorial bias
- You can publish traditional articles, null/negative results, case reports, data notes and more
- The peer review process is transparent and collaborative
- Your article is indexed in PubMed after passing peer review
- Dedicated customer support at every stage

For pre-submission enquiries, contact research@f1000.com
